MEASUREMENT OF TWO- AND THREE-PHASE RELATIVE PERMEABILITY
AND DISPERSION FOR MICELLAR FLUIDS IN
UNCONSOLIDATED SAND

BY

DONALD JAMES MacALLISTER, B. S. CHEMISTRY

THESIS

Presented to the Faculty of the Graduate School of
The University of Texas at Austin
in Partial Fulfillment
of the Requirements
for the Degree of

MASTER OF SCIENCE IN PETROLEUM ENGINEERING

THE UNIVERSITY OF TEXAS AT AUSTIN

May, 1982

ACKNOWLEDGEMENT

I thank my supervising professor, Gary Pope, for his guidance and support. I am also grateful to Dr. R. S. Schechter and Dr. B. A. Rouse for serving on my graduate committee.

Appreciation is extended to my fellow graduate students and the many undergraduate laboratory technicians who helped me. I am grateful to Mike Breland, Mojdeh Delshad, Bruce Rouse, John Trowbridge, Lorie Werts, and Vito Zapata who are more friends than colleagues.

I am especially grateful to my beautiful wife Gayle for her understanding.

ABSTRACT

Experiments in sandpacks and Berea sandstone were performed to measure dispersion and steady-state relative permeabilities. Phase behavior, interfacial tension, and viscosity determinations were made using DS-10 and TRS 10-410 surfactants to formulate a suitable three-phase micellar mixture. Relative permeability measurements were made at steady-state on both high tension brine-oil pairs and a low tension three-phase brine-oil-surfactant-alcohol mixture followed by injection of radioactive and chemical tracer(s) to investigate dispersion. The classical solution to the convection-diffusion equation for single-phase flow is generalized to multiphase flow, allowing interpretation of the multiphase flow experiments. Dispersivity was a strong function of phase, phase saturation, porous medium, and interfacial tension. Dispersivity values varied over two orders of magnitude. Extremely early breakthrough of carbon-14 tracer in the high tension oil phases was an unexpected result. Tritium tracer breakthrough curves, however, were similar to 100% saturation breakthrough curves (except for a shift due to the oil saturation). Unlike the aqueous and oleic phases, the microemulsion phase dispersivity was not a function of saturation. Three-phase experiments indicated that the aqueous or oleic phase relative permeability is a function of its own saturation only. During three-phase flow, a change in wettability from the original water-wet state occurred.

INTRODUCTION

Among the approximations commonly made in constructing a chemical flood simulator are theoretical relative permeability curves of micellar fluid phases and negligible dispersion (or artificially-produced dispersion such as numerical dispersion). Errors in these approximations can lead to erroneous and misleading results, especially in compositional simulators¹ and when applying fractional flow theory.^{2,3}

The objective of this study is to determine the relative permeability and dispersion in one-, two-, and three-phase flow for a three-phase micellar fluid composition. These data can then be incorporated into a chemical flood simulator so that more accurate predictions can be made.

To fulfill this objective, this investigation consists of five sections: the theoretical background of relative permeability and dispersion in porous media, a description of the physical properties of the fluid compositions under consideration, a description of the experimental apparatus and experimental procedures, a discussion of the experimental results, and a discussion of conclusions drawn from experimental evidence.

THEORETICAL BACKGROUND

The theoretical background of relative permeability and dispersion in porous media is an integral, although sparsely researched, aspect of chemical flooding. First, this chapter reviews relative permeability, its definition, the properties of high and low interfacial tension two-phase relative permeabilities, and the application of relative permeability to mobility design. Secondly, dispersion in porous media is discussed including its definition, single-phase dispersion, a theory for partitioning of tracers into multiple phases, two-phase dispersion, and, finally, three-phase dispersion.

Relative Permeability

Permeability is an average (macroscopic) property that measures the ability of a porous medium to transmit fluid. When two or more immiscible fluids are simultaneously flowing in a porous media, interference occurs which reduces the effective permeability of each fluid. This permeability reduction gives rise to the following relative permeability concept:

$$k_{r_j} = k_{e_j} / k \quad 2.1$$

Due to fluid-fluid interference, relative permeability is a function of fluid saturation.⁴⁻⁵ Figure 5.16

illustrates typical relative permeability curves. The relative permeability of the non-wetting phase at residual wetting phase saturation is always greater than the relative permeability of the wetting phase at residual non-wetting phase saturation.

The rapid decline of wetting phase relative permeability indicates that the larger pores are occupied first by the non-wetting phase.⁴ As the non-wetting phase saturation increases, the average pore size saturated by the wetting phase decreases. As a result, the non-wetting phase occupies larger pores than the wetting phase. Oil/brine relative permeabilities, with high interfacial tension (IFT), exhibit a hysteresis effect for desaturation and resaturation processes.

Bardon and Longeron⁶ studied a two-phase oil/vapor system and determined that oil/vapor relative permeabilities are independent of velocity. Two-phase oil/brine relative permeabilities are also independent of velocity except close to residual oil and residual brine saturations.^{7,8} This exception is due to the dependence of residual oil and residual brine saturations on the capillary number, which is proportional to fluid velocity, and defined by the following ratio:

$$N_c = \frac{v\mu}{\sigma}$$

Interfacial tension-lowering additives have several effects on two-phase relative permeabilities:

Critical Interfacial Tension

Leverett⁹ added amyl alcohol to a kerosene/7N sodium chloride solution to lower the IFT from 30 dynes/cm to 5 dynes/cm. This caused a small but significant increase in both oil and brine relative permeabilities in high permeability sandpacks. Amaefule and Handy⁷ found a critical IFT occurs at 10^{-1} dyne/cm where an increase in relative permeability is apparent for several oil/brine/low concentration surfactant formulations in Berea sandstone. Bardon and Langeron⁶ found a critical IFT of 0.04 dyne/cm is necessary to increase the relative permeabilities of a n-heptane/methane formulation at 71.1°C and 5,800 psig in Fountainebleau sandstone.

Klaus¹⁰ found that aqueous phase relative permeability increased with decreasing IFT over the entire IFT range for soltrol 170/2.0 wt % calcium chloride brine/isopropyl alcohol two-phase compositions in Berea sandstone. Oleic phase relative permeability increased with decreasing IFT below 1.6 dynes/cm. Above 1.6 dynes/cm no change in oleic phase relative permeability occurred.

Residual Saturations

As noted earlier, residual oil and residual brine saturations decrease with increasing capillary number.

Since the capillary number is inversely proportional to IFT, residual oil and residual brine saturations should decrease with the addition of IFT-lowering additives. Several investigators^{7,10-12} have confirmed this decrease.

Curvature

Relative permeability curvature decreases with decreasing IFT and tends to become a linear function of saturation as IFT approaches zero.^{7,12,13} Batycky and McCaffery¹⁴ observed this effect for n-decane/1.0 wt % NaCl brine/0.2 wt % TRS 10-80 two-phase compositions at 26.6°C in unconsolidated sand. Some curvature still exists at 0.02 dynes/cm indicating some interference between the fluids. Batycky and McCaffery postulate that only when residual oil and residual brine saturations are zero will wettability-determined preferential flow paths be eliminated and straight relative permeability curves occur. This postulation is confirmed for one case by Bardon and Longeron⁶ who studied n-heptane/methane relative permeabilities. Relative permeability curves became straight lines at 10^{-3} dynes/cm where the residual oil and residual brine saturations were zero.

Hysteresis

At high IFT, relative permeability may be different for imbibition and drainage processes. This phenomenon is called hysteresis. Amaefule and Handy⁷ found that hysteresis tends to diminish with decreasing IFT and is almost non-existent at ultra-low IFTs for several oil/brine/surfactant formulations in Berea sandstone. Batycky and McCaffery¹⁴ observed the same effect for an n-decane/1.0 wt % NaCl brine/0.2 wt % TRS 10-80 two-phase fluid composition at 26.6°C in unconsolidated sand. Talash¹³ reports similar results for two-phase crude oil/field brine compositions with four different low-concentration surfactants in Berea sandstone. Klaus,¹⁰ on the other hand, found little or no change in relative permeability hysteresis with decreasing IFT for soltrol 170/2.0 wt % calcium chloride brine/isopropyl alcohol two-phase compositions in Berea sandstone. The absence of hysteresis may be due to an insufficiently decreased capillary number.

Wettability

The shape of relative permeability curves is dependent on the porous media wettability.^{11,12,15,16} In addition, the nonwetting phase displacing the wetting phase leaves a lower residual saturation than the reverse.^{11,12,16} Amaefule and Handy⁷ determined that Berea sandstone surfaces were less water wet after flooding with sulfonate. This effect is

evident in the relative permeability curves for fluids containing IFT-lowering additives for Berea sandstone,¹⁰ polytetrafluoroethylene cores,¹¹ and unconsolidated sand.¹⁴

Mobility

Gogarty et al^{17,18} investigated the effect of relative permeability in secondary and tertiary flooding. Gogarty utilized the mobility and total relative mobility concepts as a basis for field flood design. Mobility and total relative mobility are defined as follows:

$$M = \frac{k_e}{\mu} \quad 2.3$$

$$M_{rT} = \sum_{j=1}^3 \frac{k_{rj}}{\mu_j} \quad 2.4$$

A minimum total relative mobility value is determined by plotting total relative mobility vs aqueous saturation (Figure 5.2). The minimum total relative mobility is used as a criterion for designing a fluid to efficiently displace an oil/brine bank. Chang et al¹⁹ recently applied the minimum total relative mobility criterion in designing the mobility requirements of the El Dorado micellar-polymer demonstration project.

Dispersion in Porous Media

Consider a single fluid containing a non-adsorbing solute tracer and flowing through a porous medium. The

tracer is identified by a physical property (radioactivity, color, etc.). As flow proceeds, the tracer spreads and forms an ever-widening transition zone of tracer concentration varying from injected concentration to zero. The transition zone extends beyond the region it is expected to occupy according to the average flow alone. When a small slug of fluid containing tracer is injected, a bell-shaped pulse forms. The height of the pulse decreases and its width increases as flow proceeds. This spreading of the tracer is termed dispersion.

Dispersion in Single-Phase Flow

This discussion considers only one-dimensional miscible dispersion of a liquid phase in porous media. For these assumptions, the material balance equation is:

$$\frac{\partial C_T}{\partial X} + \frac{q}{A\phi} \frac{\partial C_T}{\partial X} = \frac{\partial}{\partial X} \left(K_1 \frac{\partial C_T}{\partial X} \right) \quad 2.5$$

As outlined by Perkins and Johnston,²¹ dispersion in porous media during laminar flow can be characterized by the dispersion tensor, \underline{K} , as follows:

$$\underline{K} = \begin{pmatrix} K_t & 0 & 0 \\ 0 & K_t & 0 \\ 0 & 0 & K_l \end{pmatrix} \quad 2.6$$

(The axis is aligned with the flow.)

$$K_l = \frac{D_0}{F\phi} + \alpha_l v^\beta \quad 2.7a$$

$$K_t = \frac{D_0}{F\phi} + \alpha_t v^\beta \quad 2.7b$$

Several authors^{20,22-25} have demonstrated that at frontal advance rates on the order of 0.5 to one foot per day the second term dominates for longitudinal dispersion. The magnitude of β varies between 1.0 and 1.4 with 1.2 considered a reasonable value for sandstone.^{20,21,23,26}

For simplicity β is often assumed to be 1.0. This assumption, for the case where the second term of Equation 2.6 dominates, implies that longitudinal dispersion is proportional to velocity. This has been confirmed by several investigators.^{24,26-28} At very low flow rates, dispersion is equal to the Fick's diffusion coefficient reduced by the factor $F\phi$. The factor $F\phi$ accounts for the tortuosity of the porous media.²⁵ In addition, longitudinal dispersivity is on the order of 30 times greater than transverse dispersivity.^{21,25}

Normalize distance, time, and concentration as follows:

$$X_D = \frac{X}{L} \quad 2.8$$

$$t_D = \frac{tq}{AL\phi} \quad 2.9$$

$$C_D = \frac{C_T}{C_0} \quad 2.10$$

The material balance equation now becomes:

$$\frac{\partial}{\partial t_D} C_D + \frac{\partial}{\partial X_D} C_D = \frac{K_1}{v_{TL}} \frac{\partial^2}{\partial X_D^2} C_T \quad 2.11$$

The well-known solution to Equation 3.7 for the following boundary conditions:

$$C_D = 0 \quad X_D \rightarrow \pm \infty \quad 2.12$$

is:

$$C_D = \frac{1}{2} \left[1 - \operatorname{erf} \left(\frac{X_D - t_D}{\sqrt{\frac{4K_1 t_D}{v_{TL}}}} \right) \right] \quad 2.13$$

All of our measurements are performed on samples produced from the outflow end of the porous media ($X_D = 1$), therefore, Equation 3.9 is rewritten as:

$$C_D = \frac{1}{2} \left[1 - \operatorname{erf} \left(\frac{1}{\sqrt{\frac{4K_1}{v_{TL}}}} \cdot \frac{1 - t_D}{\sqrt{t_D}} \right) \right] \quad 2.14$$

Brigham et al²⁰ outlined a method of calculating longitudinal dispersion from experimental data for single-phase miscible displacement. Their analysis assumes longitudinal dispersion is governed by Equation 2.5. This equation is analogous to Fick's diffusion equation²¹ with the dispersion coefficient substituted for the diffusion coefficient. Perkins and Johnston²¹ further modified the approach and illustrate how longitudinal dispersion can be calculated by

plotting normalized concentration against a function λ on probability paper. The function λ is defined as follows:

$$\lambda = \frac{t_D - 1}{\sqrt{t_D}} \quad 2.15$$

This plot yields a straight line for fluids conforming to Equation 2.14. The longitudinal dispersion coefficient can then be calculated by graphically determining λ_{90} (λ at 90% of full strength effluent concentration) and λ_{10} from the best straight line through the data as follows (Figure 5.22):

$$K_1 = v_T L \left(\frac{\lambda_{90} - \lambda_{10}}{3.625} \right)^2 \quad 2.16$$

or

$$\alpha_1 = L \left(\frac{\lambda_{90} - \lambda_{10}}{3.625} \right)^2 \quad (\beta = 1.0) \quad 2.17$$

Note that at one pore volume ($t_D = 1$), $\lambda = 0$ and Equation 2.14 reduces to $C_D = 1/2$. Therefore, the 50% of full strength concentration will be produced at $t_D = 1$.

Tracer Partitioning

A tracer, when added to either the oleic or aqueous phase in a three-phase micellar fluid formulation, will partition into the microemulsion phase since all components of both oleic and aqueous phases are also in the microemulsion phase. As a result, tracer production data in which partitioning occurs must be corrected. This section develops

a theory to account for two-phase partitioning of micellar fluids.

The flow of tracer through a porous medium is not pistonlike. The breakthrough time of tracer, t_D^{Bt} , will be defined as the time at which the tracer concentration reaches 50% of its injected value since this corresponds to the time at which a truly pistonlike concentration change would occur. Note this is true only for a symmetrically-produced concentration profile.²⁹ The breakthrough time for a nonpartitioning tracer in a phase whose velocity is defined as:

$$v_{Tj} = \frac{q f_j}{A \phi S_j} \quad 2.18$$

is given by:

$$t^{Bt} = \frac{L}{v_{Tj}} \quad 2.19$$

Normalizing using Equation 2.9 yields:

$$t_D^{Bt} = S_j / f_j \quad 2.20$$

Note that phase saturation can be calculated from tracer data since both t_D^{Bt} and f_j are known.³⁰

Neglecting dispersion, the material balance equation for a partitioning tracer at steady state is:

$$\phi A \frac{\partial}{\partial t} (S_1 C_{T_{11}} + S_2 C_{T_{12}}) + q \frac{\partial}{\partial X} (f_1 C_{T_{11}} + f_2 C_{T_{12}}) = 0 \quad 2.21$$

Define a tracer partition coefficient as follows (for tritium tracer):

$$K_{T1} = \frac{C_{T12}}{C_{T11}} \quad 2.22$$

Assume K_{T1} is constant (this is true under some conditions e.g., radioactive tracers,³⁰ see Table 5.17).

Equation 2.21 now becomes:

$$(S_1 + S_2 K_{T1}) \frac{\partial C_{T11}}{\partial t} + \frac{q}{A\phi} (f_1 + f_2 K_{T1}) \frac{\partial C_{T11}}{\partial X} = 0 \quad 2.23$$

and

$$\left(\frac{\partial X}{\partial t} \right) C_{T11} = \frac{q}{A\phi} \left(\frac{f_1 + f_2 K_{T1}}{S_1 + S_2 K_{T1}} \right) \quad 2.24$$

Employing Equations 2.9, 2.18, and 2.19, the breakthrough time is:

$$t_D^{Bt} = \frac{S_1 + S_2 K_{T1}}{f_1 + f_2 K_{T1}} \quad 2.25$$

Analyses leading to equations similar to these have been performed by Pope¹ and Deans,³⁰ who appears to be the first to propose the use of tracers in relative permeability experiments. Since K_{T1} , f_1 , and f_2 are measured, there is only one unknown in Equation 2.25 since $S_1 + S_2 = 1$. (This is not true when three phases are present, however.) When phase two is not flowing (at residual saturation S_{2r}), Equation 2.25 reduces to:

$$t_D^{Bt} = S_1 + S_2 r K_{T1} \quad 2.26$$

Dispersion in Two-Phase Flow

For two-phase flow with a partitioning tracer, the material balance for a tracer undergoing dispersion is: (Note that the theory is developed for aqueous phase ($j = 1$) and microemulsion phase ($j = 3$) with a partitioning tritium tracer ($i = 1$) but could be developed for any two phases with an appropriate partitioning tracer.)

$$\begin{aligned} \phi A \frac{\partial}{\partial t} (S_1 C_{T_{11}} + S_3 C_{T_{13}}) + q \frac{\partial}{\partial X} (f_1 C_{T_{11}} + f_3 C_{T_{13}}) = \\ A \phi \frac{\partial}{\partial X} \left(S_1 K_{11} \frac{\partial C_{T_{11}}}{\partial X} + S_3 K_{13} \frac{\partial C_{T_{13}}}{\partial X} \right) \end{aligned} \quad 2.27$$

For the same assumptions stated in the single-phase flow section and assuming steady state flow (saturations and fractional flows constant) the material balance equation is:

$$\begin{aligned} (S_1 + S_3 K_{T1}) \frac{\partial C_{T_{11}}}{\partial t} + \frac{q}{A \phi} (f_1 + f_3 K_{T1}) \frac{\partial C_{T_{11}}}{\partial X} = \\ (S_1 K_{11} + S_2 K_{13} K_{T1}) \frac{\partial^2 C_{T_{11}}}{\partial X^2} \end{aligned} \quad 2.28$$

Normalizing using Equations 2.9 and 2.10 and a new normalized time variable:

$$t_{Dt} = \frac{qt f_1}{AL\phi S_1} = \frac{t_D}{(S_1/f_1)} \quad 2.29$$

yields:

$$\frac{\partial C_{D11}}{\partial t_{Dt}} + \frac{\partial C_{D11}}{\partial X_D} = \frac{\bar{K}_1}{v_{TL}} \frac{\partial^2 C_{D11}}{\partial X_D^2} \quad 2.30$$

$$v_T = \frac{q}{A\phi} \frac{f_1 + f_3 K_{T1}}{S_1 + S_3 K_{T1}} \quad 2.31$$

$$\bar{K}_1 = \frac{S_1 K_{11} + S_3 K_{13} K_{T1}}{S_1 + S_3 K_{T1}} \quad 2.32$$

$$\bar{\alpha}_1 = \frac{S_1 \alpha_{11} + S_3 \alpha_{13} K_{T1}}{S_1 + S_3 K_{T1}} \quad 2.33$$

As before, at $X_D = 1$:

$$C_{D11} = 1/2 \left[1 - \operatorname{erf} \left(\frac{1 - t_{Dt}}{\sqrt{\frac{4K_{11} S_1 t_{Dt}}{f_1 v_{TL}}}} \right) \right] \quad 2.34$$

and

$$\bar{K}_1 = v_{TL} \left(\frac{\lambda_{190} - \lambda_{110}}{3.625} \right)^2 \quad 2.35$$

$$\bar{\alpha}_1 = L \left(\frac{\lambda_{190} - \lambda_{110}}{3.625} \right)^2 \quad 2.36$$

where

$$\lambda_1 = \frac{t_{Dt} - 1}{\sqrt{t_{Dt}}} \quad 2.37$$

Equation 2.37 adjusts λ_1 so that t_{Dt}^{Bt} occurs at $\lambda_1 = 0$. Brigham²⁹ discusses why this is necessary.

Using different nomenclature, Stalkup³¹ modified Equation 2.15 for miscible oleic phase displacements of several hydrocarbons (including propane) performed in the presence of 0.5 wt % CaCl_2 brine in Boise, Berea, and Torpedo sandstones, where t_D^{Bt} occurs at less than one pore volume ($t_D < 1$) as follows:

$$\lambda_f = \frac{\frac{V}{V_{pf}} - 0.5}{\left(\frac{V}{V_{pf}}\right)} \quad 2.38$$

V = produced oleic phase volume = qtf_o

V_{pf} = total mobile oleic phase volume = $AL\phi S_o$

or

$$\lambda_f = \frac{\frac{qtf_o}{AL\phi S_o} - 0.5}{\left(\frac{qtf_o}{AL\phi S_o}\right)} \quad 2.38a$$

Applying Equations 2.9 and 2.29:

$$\lambda_f = \frac{t_{Dt} - 1}{\sqrt{t_{Dt}}} \quad 2.39$$

Note that in light of Equation 2.39, Equation 2.38 is merely a special case of Equation 2.37 for oleic phase flowing at residual aqueous phase. Similarly Equation 2.37 reduces to Equation 2.15 for $S = 1$ and $f = 1$.

The measured dispersivity ($\bar{\alpha}_i$) is a weighted average of the actual phase dispersivities. (Note that for single-phase flow, Equation 2.33 reduces to $\bar{\alpha} = \alpha$.) Saturations are determined by Equation 2.25 and by material balance calculation and K_{Ti} is measured for static fluid samples. This leaves two unknowns in Equation 2.33 (α_{11} and α_{13}). Therefore, in order to determine the actual phase dispersivities where $K_{Ti} \neq 0$, two tracers are required. As illustrated in Figure 5.63, the data often deviate from an S-shaped convective configuration indicating a departure from Equation 2.5. This occurrence has been observed by several investigators^{21,24,29,32-34} with a variety of explanations. The phenomenon is more severe in the presence of another immiscible phase. It is also associated with early breakthrough of the nonwetting phase coupled with a long "tailing out" of nonwetting phase concentration. This has been attributed to a stagnant volume of nonwetting fluid trapped by wetting phase as discontinuous masses or in "dead end pores" and "dendritic structures." This stationary volume is gradually replaced by molecular diffusion. The tailing out is due to the slowness of the diffusion process relative to the convective process. The fact that the tailing out is less pronounced at a lower fluid velocity has lead some investigators^{24,33} to conclude that a diffusion process is indeed responsible.

Coats and Smith³² have constructed a three-parameter capacitance model that assumes a stagnant volume in communi-

cation with the mobile fraction by a first-order rate expression. Besides the longitudinal dispersion coefficient (K_1), additional parameters of flowing fluid fraction and mass transfer coefficient describe the displacement. For experimental data exhibiting early, asymmetrical production, the capacitance model better fits the data. Also, the capacitance model very nearly approximates those production curves matched closely by the convective model. The capacitance model separates the dispersion process from the capacitance effect. For this reason, the dispersion coefficient calculated by the capacitance model for early, asymmetrical production is smaller than that calculated by the convective model. Similar capacitance effects are discussed by Spence and Watkins²³ for limestone and Donaldson et al³⁵ for sandstone.

Thomas et al³⁴ found that dispersion in the wetting phase increases with decreasing wetting phase saturation in Boise sandstone at room temperature. Nonwetting phase dispersion was determined by a unique method. Boise sandstone was saturated at elevated temperature with hot liquid paraffin representing a wetting phase. Air was then injected to reduce the paraffin to a residual saturation. Different air pressures were applied to vary the residual paraffin saturation. After cooling to room temperature, the air was displaced with brine, which simulates a nonwetting

phase. The resulting nonwetting phase dispersivities increased with decreasing nonwetting phase saturation.

Schuler²⁴ performed wetting phase miscible displacements in Berea sandstone at several wetting phase saturations. Longitudinal dispersion increased not only with velocity, but with decreasing wetting phase saturation as well. Raimondi et al³³ also observed an increase in non-wetting phase dispersion with decreasing nonwetting phase saturation for ethylbenzene displacing heptane and 8.0 wt % NaCl brine displacing 3.0 wt % brine at room temperature in Berea sandstone. A variance in the wetting phase dispersivity is apparent, but no coherent relationship with phase saturation exists. Stalkup³¹ also reported increased dispersion in the nonwetting phase with decreasing non-wetting phase saturation for several hydrocarbons and 0.5 wt % CaCl₂ brine in several sandstones. Longitudinal dispersion coefficients divided by phase velocity and by the dispersion coefficient at 100% phase saturation are plotted vs phase saturation for the nonwetting phase in Figure 2.1 and for the wetting phase in Figure 2.2 for the variety of fluids and sandstones reported. Figure 2.1 gives a clear indication of the increased dispersion with decreasing nonwetting phase saturation. Figure 2.2 gives the same indication for the wetting phase from data reported by Schuler²⁴ and Thomas et al.³⁴ The

data of Raimondi et al³³ show no correlation. No mention of dispersion in low tension systems was found in the literature.

Dispersion in Three-Phase Flow

For the tracers used in this investigation, partitioning occurs only between excess brine and microemulsion and excess oil and microemulsion. Since none of the tracers partition to all three phases, the equations developed for two-phase flow apply. The only difference is that $S_1 + S_2 \neq 1$ and $f_1 + f_2 \neq 1$. There are three average dispersivity equations (Equation 2.33) for three phases and three unknowns (α_1 , α_2 , and α_3). Therefore, three tracers are required. In addition, at least two equations like Equation 2.25 are required to calculate saturation from tracer breakthrough data. Two tracers would appear to be sufficient for this purpose since the three saturations must add to unity and two t_D values can be measured, one for each tracer. This gives two equations and two unknowns (any two of the three saturations). However, unlike the two-phase cases, no independent tracer calculation is possible unless a third, non-partitioning tracer is used.

PHYSICAL SYSTEM

Phase behavior, interfacial tension (IFT), and viscosity are physical properties especially important in porous media flow experiments. In this chapter a brief introduction to phase behavior, IFT, and viscosity is presented followed by physical property data for Siponate DS-10 (sodium dodecyl benzene sulfonate) and Witco TRS 10-410 (a petroleum sulfonate).

As Figure 3.1 illustrates, three typical phase types are formed with changing salinity for surfactant/alcohol/oil/brine fluid compositions. At high surfactant concentration, all phase environments ideally are single phase. At lower surfactant concentration, three phase types exist. As indicated by the tie-lines in Figure 3-1, Type II⁽⁺⁾ contains a two-phase region which is composed of an aqueous phase rich in amphiphilic species and containing some solubilized oil, and an oleic phase of almost pure oil. Type II⁽⁻⁾ contains a two-phase region which is composed of an oleic phase rich in amphiphilic species and containing some solubilized brine, and an aqueous phase of almost pure brine. Type III contains the same two-phase regions, corresponding to Types II⁽⁺⁾ and II⁽⁻⁾ described above, and an additional three-phase region containing an oleic phase, an aqueous phase, and a middle (microemulsion) phase composed of the amphiphilic species and solubilized oil and brine. These trends have been discussed by many authors.^{36-39,42-46}

Healy and Reed³⁸ demonstrated that the most efficient oil recovery occurs at or near the salinity where oleic/microemulsion phase IFT (γ_{mo}) and aqueous/microemulsion phase IFT (γ_{mw}) are equal and low. This salinity is, by one definition, the so-called optimal salinity for oil recovery. This salinity is close to the salinity at which the middle phase solubilizes equal volumes of oil and brine, which is another definition of optimal salinity.

Viscosity is important in calculating mobility, total relative mobility, and permeability. The first two are discussed in Chapter Two, Equations 2.3 and 2.4. Viscosity enters into the well-known Darcy equation⁴⁰ for calculating relative permeability as follows:

$$kk_{rj} = \frac{L_{\mu j} U_j}{\Delta \phi_j} \quad 3.1$$

Siponate DS-10, a highly purified sulfonate, was considered since its purity would facilitate analysis of effluent samples. Siponate DS-10 was investigated in combination with two alcohol co-surfactants, brine and iso-octane.

Unfortunately, DS-10 exhibited unacceptable phase behavior. Spontaneous precipitation was observed in some instances when samples equilibrated at elevated temperatures were opened at room conditions. This result was obtained by mixing various solutions containing sulfonate in screw-top vials and measuring their properties as outlined in the next

chapter. The cause of the precipitation is unknown but may be related to thermodynamic instability at lower temperature and/or upon exposure to oxygen.

Siponate DS-10 samples containing s-pentanol and t-pentanol co-surfactants were equilibrated at 50°C. Both phase volume diagrams (Appendix 1) and pseudo-ternary diagrams (Appendix 2) were constructed.

The phase volume fractions for a 5.0 volume % DS-10, 5.0 volume % s-pentanol, 45.0 volume % iso-octane, 45.0 volume % NaCl brine composition are illustrated in Figure 3-2. One three-phase sample was observed at 3.0 wt % NaCl. Pseudo-ternary diagrams with iso-octane, 1:1 Siponate DS-10:s-pentanol, (by volume assuming 1.0 g/cm³ sulfonate density), and brine pseudo-components are illustrated in Figures 3.3 to 3.6. The ternary diagram for 0.5 wt % NaCl (Figure 3.3) reflects suitable Type II(-) behavior. Problems occur with the 1.0 wt % NaCl compositions (Figure 3.4). Although Type III phase behavior is apparent, gels and precipitates developed as indicated. Type II(+) phase behavior is reflected in Figure 3.5 for 3.0 wt % NaCl and in Figure 3.6 for 6.0 wt % NaCl. Acceptable pseudo-ternary behavior is exhibited at 3.0 wt % NaCl but not at 6.0 wt % NaCl where departure from ideal pseudo-ternary behavior occurs on the brine/surfactant: alcohol axis. In this region, two-phase samples occur with s-pentanol apparently acting as an excess oleic phase.

In addition to the anomalous pseudo-ternary phase behavior encountered at 1.0 wt % NaCl and 6.0 wt % NaCl, difficulties occurred when viscosity measurements were attempted at room conditions. Many microemulsions became gel-like in the viscometer cup (marked "G") causing readings to go off scale. Soap-like bubbling also occurred, causing erratic and inconsistent viscometric measurements.

In light of these difficulties, samples were mixed using t-pentanol in place of s-pentanol. A phase volume fraction diagram appears in Figure 3.7. This diagram is more encouraging than Figure 3.2 because the middle phase microemulsion solubilizes greater volumes of oil and water. Unfortunately, problems develop with pseudo-ternary behavior. Figure 3.8 illustrates a pseudo-ternary phase diagram for 2.0 wt % NaCl. Precipitates or gels formed in the vials indicated.

At this point, investigation of Siponate DS-10 was suspended in favor of Witco TRS 10-410, a petroleum sulfonate investigated by Glinnsmann and Hedges^{39,41} and many others.^{28,42-46}

A fluid composition of 47.0 volume % of a 1.1 wt % NaCl brine, 1.5 volume % iso-butanol, 1.5 volume % of active TRS 10-410 sulfonate, and 50.0 volume % n-decane was determined to have acceptable physical properties. A volume fraction diagram appears in Figure 3.9. At 1.1 wt % NaCl almost equal volumes of oil and water are solubilized into

the microemulsion phase. Figure 3.10 represents a Type III pseudo-ternary for 1.1 wt % NaCl brine. Interfacial tension as a function of salinity is plotted in Figure 3.11. At the optimal salinity of 1.1 wt % NaCl the IFT curves intersect at 10^{-3} dyne/cm. Viscosity data are illustrated in Figure 3.12. Viscosity is essentially constant at 1.1 wt % NaCl brine for shear rates greater than 1.0 sec^{-1} . Additional data at different salinities and with different oils, sacrificial agents, and alcohol co-surfactants are available.^{28,41,47,48}

EQUIPMENT AND PROCEDURES

The major components of the flow apparatus as well as the analytical instruments used in characterizing the injected and produced fluids are briefly described. The experimental and analytical procedures employed are outlined next. Additional information for some of the equipment used is available.^{28,47,48} Equipment manufacturers are listed in Table 4.1

A schematic diagram of the three-phase steady state flow apparatus appears in Figure 4.1. The major components are constant rate pumps, fluid reservoirs, porous medium, pressure detecting and recording equipment, sample collector, and temperature-controlled air bath.

Constant Rate Pump

Cheminert model CMP-2 metering pumps were employed in all flow experiments. The Cheminert pumps possess two rate selection potentiometers; one selects the maximum pump delivery rate (0.2, 0.4, 0.5, 1, and 2 ml/min), the second selects the fraction of the maximum flow rate. Although this fractional range is from .001 to 1.0, the practical rate selection limits are approximately 0.02 ml/min to 2.0 ml/min. Note that the pumps were not calibrated and flow rate was calculated from effluent production for each phase cut. The Cheminert pump has three independent pump chambers which are composed of a cylinder (Kel-F), piston

(glass), and seal (Teflon). Two of the pistons are 180° out of phase to minimize pulsing. The third acts as a filling pump. Maximum output pressure is 500 psi. Due to swelling of Kel-F cylinders upon contact with some hydrocarbons only distilled water, brine, or equilibrated aqueous phases were pumped through the pistons. Piston cycles are coordinated with pneumatic valves which are switched from inlet to discharge. For this reason, a 60 psi compressed gas source is necessary for pump operation.

Fluid Reservoir

Glenco Chromatographic Series 3400 and 3500 glass columns were employed as fluid reservoirs. The column is 2.0 inches in diameter by 24.0 inches long with a volume of 1235.6 ml. The columns are constructed of borosilicate glass with polypropylene collars and end pieces. These reservoirs allow visualization of fluid levels and detection of air bubbles but are rated only to 80 psi. The Series 3500 end pieces are Teflon and are resistant to hydrocarbon swelling when in contact with the oleic and microemulsion phases. In addition, a vent plug in the end piece allows air to be easily removed from the column. Teflon pistons 2.0 inches thick by 1 15/16 inch diameter were cut in the University of Texas Petroleum Engineering Department. Two O-ring grooves are cut to fit two Parker 125 O-rings, providing a double seal and preventing torsion of the

piston as it moves. The pistons are necessary to prevent contact of the pump drive fluid and the injected fluids.

Porous Media

Sandpacks and Berea sandstone were employed in this investigation. Berea sandstone (2.0 inches square) was cut to a 24.0 inch length. End pieces consisted of a 2.0 by 2.0 inch square of nylon screen (500 micron pore size) placed between the sandstone and a 2.0 by 2.0 inch square plexiglas end piece drilled and tapped in the center to accomodate a 1/8 inch NPT nylon Swagelok male connector. Connectors of the same size were used 6.0 inches from each end of the sandstone to serve as intermediate pressure taps. The taps and end pieces were held in place by three coats of epoxy (Appendix 3) which also served to seal the sandstone and confine injected fluids. Details of the epoxy procedure are contained in Appendix 3.

The sandpacks utilized in Experiments OWCL and OW were packed in Glenco Chromatographic glass columns (see Fluid Reservoir section). These columns are identical to the Series 3400 columns used as reservoirs except that the internal diameter is 1.0 inch. The packing procedure for sandpacks is outlined later in this chapter. The glass columns allow visualization of the fluids but are limited to 80 psi pressure and have no intermediate pressure taps.

Experiments OWZ, MO, MW, and PH3 were conducted in unconsolidated sand packed in a 2.0 inch internal diameter by 24.0 inch long stainless steel column. Details of the sand modification, cleaning and packing procedures appear later in this chapter. The column consists of 1/8 inch NPT male connectors, threaded endcaps, stainless steel mesh supports, 10 μ m screens, O-rings, threaded steel column, and 1/8 inch tube fittings. Intermediate pressure ports are installed every 6.0 inches. End pieces are screwed on and form an O-ring seal. The column has been pressure tested successfully up to 1,000 psi.

Pressure Detecting and Recording Equipment

Diaphragm-type pressure transducers were employed for all pressure measurements. Diaphragm-type transducers consist of rigid, fixed supports holding a magnetically permeable metal plate which deforms under a pressure differential. The magnetic inductance changes as the gap between support and deformable plate changes. The inductance is converted by an AC bridge to a voltage proportional to the applied pressure differential. Validyne model DP15 transducers were used with 80, 50, 10, 5, and 1 pounds per square inch maximum pressure differential transducer plates. A model MC 1-10 module case holding up to ten Validyne CD-19 demodulators was used. Each demodulator has a six position gain switch and a gain potentiometer. The voltage

position gain switch and a gain potentiometer. The voltage is converted to a DC signal which is recorded by a Texas Instruments multipoint self-balancing recorder. The recorder is capable of recording on twelve separate channels. The pressure measuring apparatus is calibrated as follows:

1. Apply pressure equal to full scale (measured by a known, accurate source, such as a mercury manometer).
2. Adjust gain on the demodulator to register full scale on the recorder.
3. Release pressure and adjust zero settings.
4. Repeat Steps 2 and 3 until no adjustment is necessary.
5. Check at least three intermediate pressures to check linearity of pressure response.

Fraction Collector

Incremental volumes collected for an adjustable time interval were obtained with an Isco model 328 fraction collector. Time intervals from 0.1 to 99.9 minutes in increments of 0.1 min (6 sec) are available. Graduated test tubes of 15 ml or 10 ml volume in 0.1 ml increments were utilized.

Temperature-Controlled Air Bath

Flow experiments conducted at 30°C were performed in a fiberglass hood. The hood is 72.0 inches long by 60.0 inches high by 36.0 inches deep outside dimensions, and consists of 0.5 inch urethane sandwiched between two 1/8-inch thick fiberglass sheets. Access to the inside is gained through a vertically sliding glass door 60.0 inches long and 30.0 inches high. The hood is heated by two heaters controlled by an Athena model 74-6 proportional band temperature controller (0 to 300°F) and a continuously running blower for each heater. Temperature is monitored by a mercury thermometer.

Several components and properties of both injected and produced fluids were analyzed including water, isobutanol, decane, and nonane concentration (gas chromatography); calcium ion concentration (atomic absorption); radioactivity (scintillation counter); viscosity (viscometer); and IFT (spinning drop interfacial tensiometer). A brief description of each of these instruments follows.

Gas Chromatography

A Tracor Model 560 gas chromatograph with a Model 770 auto sampler was employed to analyze water, isobutanol, nonane, and decane. Samples are vaporized and passed through a thermal conductivity detector for water analysis followed by flame ionization. The flame ionization detector

detects nonane, decane, and isobutanol. Table 4.2 lists operating conditions for the 36.0 inch by 1/8 inch column packed with 80/100 Porapak Q. Standard samples are prepared and analyzed for each component each time the chromatograph is used. The standard samples allow standard curves to be constructed and quantitative interpretation to be performed.

Atomic Absorption

A Perkin-Elmer model 360 spectrophotometer with a calcium, magnesium, aluminum lamp is used to detect calcium ion concentration utilizing a standard addition technique. Two 1.5 ml aliquots of brine phase are taken. One is diluted to 25.0 ml with distilled water and the second has calcium ion added and is diluted to give 2 ppm added calcium ion. Calcium concentration in both samples is read and the concentration in the original 1.5 ml aliquot calculated.

Scintillation Counter

Radioactivity was determined for carbon-14 labelled decane (^{14}C) and tritium (T_2O) tracers employed in this investigation using a Packard model 3400 liquid scintillation counter. Scintillation samples were prepared for counting by adding 0.25 ml of the appropriate liquid phase (aqueous, microemulsion, or oleic) to 10.0 ml of scintillation cocktail

(Universal® J. T. Baker Chemical Company) and cooling for two hours prior to counting. Samples are counted at least twice for two minutes with an external standard. Previously constructed quench curves using an external standard ratio method for ^{14}C and T_2O efficiency are incorporated into a computer program which is employed to separate ^{14}C and T_2O counts and to convert raw counts into disintegrations per minute. This separation is necessary since the micro-emulsion phase often contains both tracers.

The same procedure was utilized for both tritium (T_2O) and carbon-14 (^{14}C) tracer radioactivity determinations. The concentration of ^{14}C labelled n-decane was $20\ \mu\text{Ci/ml}$ and was diluted with n-decane to about $1,100\ \text{cpm/ml}$ ($0.2\ \text{ml}$ concentrated ^{14}C to one liter of n-decane). The concentration of T_2O was $250\ \mu\text{Ci/ml}$ and was diluted with $1.1\ \text{wt } \%$ NaCl brine to about $16,000\ \text{cpm/ml}$ ($0.15\ \text{ml}$ concentrated T_2O to one liter of brine). Nonane tracer was added in the amount of $1.0\ \text{volume } \%$ to n-decane. Whenever radioactive tracer was used vinyl gloves were worn and other safety precautions observed.

1. Measure $10.0\ \text{ml}$ of liquid scintillation cocktail (Baker Universal® LSC) into $20\ \text{ml}$ polyethylene vials.
2. Pipette $0.25\ \text{ml}$ of appropriate phase into vial and securely tighten lid to avoid evaporation or spillage of radioactive material.

3. Cool samples to 5°C for two hours prior to counting to minimize chemoluminescent effects.
4. Load in scintillation counter and measure radio-activity.

Viscometer

Fluid viscosity was measured with a Contraves low shear model LS 30 viscometer. The LS 30 operates on a couette principle which analyzes stresses between two concentric cylinders. The instrument has five range settings and 30 fixed angular velocities for a shear rate range of 0.0174 to 128.5 sec^{-1} (for the available cup and bob). By multiplying shear rate by the appropriate calibration factor supplied by the manufacturer, viscosity is determined. Temperature control is maintained by a circulating water bath and monitored with a mercury thermometer placed in the viscometer cup. The operating procedure used follows:

1. Circulate water until the desired temperature is attained.
2. Place 1.0 ml of sample into the cup and insert the bob being careful to avoid air bubbles.
3. Adjust zero without rotation of the cup.
4. Take a reading at every other speed setting until reading is greater than 150.
5. Change to next higher range and repeat Step 4.

6. After all rotational speeds have been read, convert readings to viscosity with the appropriate calibration factors.

Spinning Drop Interfacial Tensiometer

Interfacial tension was measured by the method of Cayias.⁴⁹ In this technique, a small drop of the less dense liquid is placed in a bulk volume of the denser liquid in a tube. The tube is sealed and rotated along its longitudinal axis. Centrifugal force causes the drop to move to the center and elongate along the axis of rotation. For a drop whose length is greater than four times its diameter, a limiting condition is achieved and IFT is proportional to the density difference times the drop diameter squared divided by the rotational velocity to the third power. Density measurements are made with a Mettler/Paar model DMA 46 densitometer. The interfacial tensiometers were constructed by the University of Texas Department of Chemistry. Samples are spun for a minimum of eight hours or until equilibrium is achieved.

Procedures are outlined for the preparation of fluids and porous media and the experimental sequences. Preparation of samples for delineating the physical system, cleaning procedure for clay-free sand, sand packing, preparation of injection fluids, preparation of scintillation samples, determination of porous media basic properties, as well as the experimental procedures, are described.

Samples used in determining physical properties were prepared from 30.0 volume % surfactant: 30.0 volume % alcohol, and 3.695 wt % NaCl in water stock solutions. Stock solutions were prepared as follows:

1. Heat surfactant in original container in a 50°C water bath for one and a half hours.
2. Manually stir sulfonate to ensure homogeneity.
(Note Steps 1 and 2 are skipped for DS-10 since it is already homogeneous.)
3. Weigh 300 ml of active* sulfonate and 300 ml of co-surfactant based on density into a 1,500 ml Erlinmeyer flask.
4. Add distilled water to make 1,000 ml of solution.
5. Mix 15 hours by magnetic stirrer in the stoppered flask.
6. Weigh 36.95 g anhydrous NaCl into a 1,500 ml Erlinmeyer flask.
7. Add 963.05 g of distilled water to the flask.
8. Mix with a magnetic stirrer for one hour.

Physical property samples were mixed by the following procedure:

*Active refers to the amount of material that is actually sulfonate exclusive of water, unreacted oil, etc.

1. Pipette appropriate amount of 30.0 volume % surfactant (30.0 volume % co-surfactant stock) into 30 ml screwtop vials.
2. Pipette appropriate volume of distilled water.
3. Pipette appropriate volume of 3.695 wt % brine stock.
4. Pipette appropriate volume of oil and screw lid on tightly to prevent evaporation. (Note Steps 1 through 4 are performed in order since this sequence results in the fastest equilibration times.)
5. Invert vial three times to ensure mixing and place in 30°C air bath.

To remove any effect from clay, the unconsolidated sand used in Experiments OWZ, MO, MW, and PH3 was cleaned as described below:

1. Immerse sand completely in concentrated (as is) hydrochloric acid and agitate to ensure all sand surfaces are contacted.
2. Allow sand to settle for two hours.
3. Decant acid and wash repeatedly with distilled water (with agitation) until pH 7.0 is achieved. (At least ten washes are usually required.)
4. Sonify sand for two hours in distilled water.
5. Dry sand in 110°C air bath for 48 hours.

A discussion of which sands were used and why appears in the next chapter. An outline of sandpacking technique follows. The sand was packed by allowing it to fall through a series of four (for Experiments OWCL and OW) or seven (for Experiments OWZ, MO, MW, and PH3) 850 μm screens. Sand is contained in a separatory funnel reservoir and allowed to trickle out at a slow rate. The screens are held in a tube the same diameter as the column and are attached directly to one end. An FMC heavy duty vibrator is also attached to the assembly to assure an even pack. The flow of sand must be continuous during the entire packing procedure to ensure a homogeneous pack.

1. Sift sand through 150 mesh (100 micron) screen to break up any consolidation.
2. Weigh dry sand.
3. Assemble packing apparatus and use plumb-bob to make the column vertical.
4. Allow sand to fall at a slow rate with vibration.
5. Refill sand reservoir as needed to maintain continuous sand flow.
6. Stop sand flow and vibration when sand level is past the end of the column.
7. Remove screens and level sand at the end of the column with a straightedge.
8. Glue a 10 μm screen on the end of the column with silicon cement and allow to dry for 24 hours.

9. Carefully brush away all sand from threads and O-ring groove. (Stray sand grains can cause leakage.)
10. Weigh unused sand for calculation of pore volume (described later in this chapter).
11. Screw end piece with O-ring on hand tight.

Preparation of injection fluids consisted of mixing and filtering the phases of interest. Procedures for both are described. Fluids used in Experiments OWCL, OW, OWZ, and BAOW consisted of n-decane or iso-octane oil phase and various sodium chloride brines. Brine solutions were mixed on a weight percentage of salt in distilled water basis as described in the section on physical system sample preparation and will not be further discussed. Oils were used as is. Components used in mixing the three-phase micellar formulations were prefiltered. The filtering procedure follows:

1. 300 ml of fluid is loaded in a Fann model 12 BL filter container with a 0.45 micron filter (Millipore type HA).
2. The container is placed in the accompanying filter press at 40 psi.
3. Effluent is collected in a 500 ml Erlenmeyer flask.

Micellar fluids used in flow experiments were mixed from stock solutions as follows:

1. Heat TRS 10-410 surfactant in original container in 50°C water bath for 1.5 hours.
2. Manually stir surfactant to ensure homogeneity.
3. Weigh 1,935.5 g TRS 10-410, 969.6 g IBA, and 864.5 g of distilled water into a four-liter flask (Stock I).
4. Cover and stir with magnetic stirrer for 24 hours.
5. Weigh 147.46 g of anhydrous NaCl and 3,852.54 g distilled water into a second four-liter flask (Stock II).
6. Cover and stir with magnetic stirrer for two hours.
7. Dilute 800 g of Stock I with 5,000 g distilled water in an eight-liter flask to facilitate filtering (Stock ID).
8. Filter Stock ID, Stock II, and 6,000.0 g n-decane as outlined above.
9. Combine 5,437.5 g of Stock ID, 2,100.0 g of Stock II, and 5,475.0 g of n-decane to make 15 liters total in a five-gallon glass jar.
10. Cap and invert jar four times to mix components.
11. Replace cap with stopper containing two glass tubes.
12. Evacuate, invert, and place jar in 30°C air bath.
13. Allow to equilibrate for at least seven days.
14. Release vacuum, separate phases by gravity drainage and store in one-liter containers at 30°C.

The porous media is characterized by determining the porosity, permeability, and homogeneity. A procedure is outlined for this characterization.

1. Close the valve at one end of the column and cap all pressure ports.
2. Connect the other end to a vacuum pump for 30 minutes. Stop vacuum pump and monitor vacuum gauge for evidence of leakage. If no leakage is evident, restart vacuum pump.
3. Fill a Burette with the degassed saturation brine and take an initial volume reading.
4. Open closed end of column to Burette and close off vacuum.
5. Allow fluid to enter column until the level in the Burette stops changing.
6. Take final Burette reading and subtract from initial reading to obtain saturated pore volume. (This value can be compared to the bulk pore volume calculated from the weight of packed sand--Appendix 4.)
7. Calculate bulk volume (cross-sectional area times length) and determine porosity (pore volume divided by bulk volume).
8. Attach pressure monitoring equipment and brine pump and flood with brine until a steady-state pressure drop is obtained.

9. Calculate single-phase brine permeability from Darcy's law based on intermediate and total pressure taps to determine if end effects are present.
10. Flow tritium-labelled brine under steady-state conditions through the medium. Collect and analyze effluent samples.
11. Calculate saturated pore volume (Equation 2.20) as a third check of pore volume. (Note: a smooth S-shaped effluent tracer concentration curve is a good indication of homogeneity.)

An experimental procedure is outlined for dispersion and relative permeability experiments. In practice these two experiments were performed simultaneously so one outline is presented in the order that each step was carried out.

1. Pump brine phase at a constant rate through the brine saturated medium until a constant pressure drop is obtained.
2. Drain outlet line and flush inlet lines with tritiated brine.
3. Inject 1.5 pore volume of tritiated brine at the same constant rate used in Step 1 and collect effluent in graduated test tubes in a fraction collector.

4. Calculate permeability from Darcy's law using equilibrium pressure drop, average tube volume and time setting of fraction collector.
5. Drain outlet line and flush inlet line with oil phase.
6. Drive oil phase through the porous medium at 15 psid/foot while collecting all effluent (for material balance) until no more brine is produced.
7. Pump oil phase at the same constant rate as Step 1 until a constant pressure drop is obtained.
8. Drain outlet line and flush inlet lines with labelled oil phase.
9. Pump 1.5 pore volumes of labelled oil phase at the constant rate used in Step 1 and collect effluent in graduated test tubes in a fraction collector.
10. Calculate effective permeability from equilibrium pressure drop, average tube volume and time setting of fraction collector.
11. Drain outlet line and flush input lines with two or three fluid phases at the desired fractional flow.
12. Pump phases at the same total constant flow rate until a constant pressure drop is achieved and all tagged components have been displaced (check effluent radioactivity). In addition, collect all effluent for material balance until output fractional flows equal input fractional flows.

13. Drain outlet line and flush input lines with tagged phases at the same fractional flows.
14. Pump tagged phases at the previously used rate until 0.75 to 1.0 pore volume more than t_D^{Bt} of fluid (based on material balance saturations and Equation 2.20) is flushed through the porous medium. Collect effluent in graduated test tubes in a fraction collector.
15. Calculate the effective permeability of each phase from equilibrium pressure drop, average phase volumes and time setting of fraction collector.
16. Change to the next phase cuts and repeat Steps 11 through 15.
17. Analyze selected test tube samples for phase volumes, tracer concentration, IFT, calcium ion concentration, and component concentrations.

SCHEMATIC OF EXPERIMENTAL SETUP

FIGURE 4.1

EXPERIMENTAL RESULTS

The results of the seven flow experiments conducted are discussed in this chapter (Table 5.1). They consist of: 1) brine/iso-octane drainage in a high permeability sandpack with chloride ion tracer (Experiment OWCL), 2) 1.0 wt % NaCl brine/iso-octane drainage in a high permeability sandpack with tritium tracer (Experiment OW), 3) 1.1 wt % NaCl brine/n-decane imbibition in Berea sandstone with tritium and carbon-14 tracers (Experiment BAOW), 4) 1.1 wt % NaCl brine/n-decane imbibition in a low permeability sandpack with tritium, carbon-14 and n-nonane tracers (Experiment OWZ), 5) microemulsion phase/oleic phase imbibition in a low permeability sandpack with tritium and carbon-14 tracers (Experiment MO), 6) aqueous phase/microemulsion phase drainage in a low permeability sandpack with tritium and carbon-14 tracers (Experiment MW), and 7) aqueous phase/microemulsion phase/oleic phase three-phase flow in a low permeability sandpack with tritium, carbon-14, and n-nonane tracers (Experiment PH3).

Experiment OWCL

Experiment OWCL was conducted at a nominal rate of 3.5 cc/min at 27°C using a glass column packed with Oklahoma No. 1, a coarse silica sand (Table 5.2). The pack was initially saturated with 1.0 wt % NaCl brine and displaced

with 3.0 wt % NaCl brine. Chloride ion concentration was monitored with a chloride ion specific ion electrode.

Due to calibration problems, only the 100% brine saturation was monitored with the electrode. The remainder of the flow experiment was conducted using 1.0 wt % NaCl brine and iso-octane. Fluid and sandpack data are detailed in Table 5.3. The experimental results are summarized in Tables 5.4 and 5.5 and Figures 5.1 to 5.5.

Figure 5.1 reflects typical waterwet drainage relative permeability curves. The residual brine saturation is 0.149 and relative permeability to iso-octane at residual brine is 0.377. The total relative mobility curve (Figure 5.2) is also typical of a high tension, waterwet sandpack. The minimum is 0.408 cp^{-1} at 0.490 brine saturation. The experimental fractional flow diagram (Figure 5.3) is typical for high IFT fluids. The S-shaped breakthrough curve for 100% brine saturated sandpack (Figure 5.4) indicates a homogeneous pack was achieved and the breakthrough time implies that the pore volume is very close to 50.4 cc (Equation 2.9). This close agreement with the pore volume by saturation and by weight (Table 5.3) is another indication of a well-packed sandpack. The single-phase brine dispersivity is 0.250 cm (Figure 5.5).

Experiment OW

Experiment OW was conducted as a nominal rate of 2.0 cc/min at 27°C using a glass column packed with silica sand (Tables 5.2 and 5.6). The pack was initially saturated with 1.0 wt % NaCl brine. Dispersion in the aqueous phase was determined using a tritium tracer in 1.0 wt % NaCl brine for three of the six brine/iso-octane cuts (OW₁, OW₂, and OW₄). Fluid and sandpack data are given in Table 5.6. The experimental results appear in Tables 5.7 and 5.8 and Figures 5.6 to 5.15.

As expected, Figure 5.6 reflects typical waterwet drainage relative permeability curves. The residual brine saturation is 0.117 and relative permeability to iso-octane at residual brine is 0.204. The total relative mobility curve (Figure 5.7) is also typical of a high tension, waterwet sandpack. The minimum is 0.181 cp^{-1} at 0.308 brine saturation. The experimental fractional flow curve (Figure 5.8) is typical of high IFT fluids. The S-shaped breakthrough curve for 100% brine saturated sandpack (Figure 5.9) indicates a homogeneous pack was achieved and the breakthrough time implies that the pore volume is very close to 113.0 cc (Equation 2.9). The close agreement with the pore volume by saturation and by weight (Table 5.6) is another indication of a well-packed sandpack. The single-phase brine phase dispersivity is 0.342 cm (Figure 5.10). The breakthrough curve for cut OW₂ appears in Figure 5.11.

There is considerable scatter in the initial points but the S-shaped portion is reasonable. Figure 5.13 for cut OW₄ is similar. The brine saturations calculated from the breakthrough times are slightly different than saturations calculated by material balance (Table 5.7) with OW₂ being 0.071 pore volume less and OW₄ being 0.076 pore volume greater than the corresponding material balance calculations. Due to this discrepancy, all subsequent dispersions were conducted from low to high concentration. Dispersivities are 0.965 cm and 1.387 cm for OW₂ and OW₄ respectively (Figures 5.12 and 5.14 and Table 5.8). Brine phase dispersivity as a function of brine phase saturation is illustrated in Figure 5.15. Brine phase dispersivity increases as brine phase saturation decreases.

Experiment BAOW

Experiment BAOW was conducted at 2.0 cc/min nominal flow rate at 30°C using Berea sandstone (Table 5.9). The core was initially saturated with 1.1 wt % NaCl brine. Dispersion in the aqueous phase was determined using a tritium tracer in 1.1 wt % NaCl brine. Dispersion in the oleic phase was determined using carbon-14 labelled n-decane in untagged n-decane. Fluid and core data are contained in Table 5.9. The experimental results appear in Tables 5.10 and 5.11 and Figures 5.16 to 5.40.

Figure 5.16 reflects typical waterwet imbibition relative permeability curves with the high residual saturations characteristic of Berea sandstone. Figure 5.17 illustrates the same curves along with a set from another Berea experiment conducted by Deshad²⁹ using the same fluids, but in a horizontal configuration. The curves are very close except for the location of the endpoints. Total relative mobility data is illustrated in Figure 5.18. The minimum total relative mobility is 0.0498 cp^{-1} (at residual oil saturation, $S_{ro} = 0.367$). A fractional flow diagram (Figure 5.19) for both cores shows excellent correlation and also illustrates the rapid increase in brine saturation with brine phase fractional flow increasing up to 0.1. Brine phase fractional flow greater than 0.1 causes relatively small further increases in brine saturation.

Figure 5.20 demonstrates the calcium ion leaching that occurred. Initial effluent volumes contained up to 50.1 ppm calcium ion which quickly dropped to about $12.0 \text{ ppm} \pm 2.0 \text{ ppm}$ where it remained. Figures 5.21 to 5.38 contain the dispersion plots for the six different cuts used.

The narrow S-shaped curve for 100% brine saturation (Figure 5.21) indicates that the core contains no significant systematic heterogeneities and the breakthrough time implies a pore volume that is very close to 304.8 cc. The close agreement with the saturation pore volume (Table 5.9) is another indication of homogeneity. The single-phase

dispersivity is 0.128 cm (Figure 5.22). The aqueous phase dispersion curves are S-shaped and brine phase saturations calculated from frontal breakthrough (Equation 2.20) are 90% to 97% of the material balance brine phase saturations (Table 5.11). However, the n-decane dispersion curves demonstrate a skewed "capacitance"-type profile (Chapter 2). The n-decane dispersion curve at residual brine (Figure 5.23) has a breakthrough time that yields a saturation that is 97% of material balance saturation. However, oil phase breakthrough times where two phases are flowing yield oil phase saturations much less than material balance saturations. Brine and oil phase dispersivities as a function of brine phase saturation are illustrated in Figure 5.39. For both phases, dispersivity increases as phase saturation decreases. Dispersivities for the Berea core Delshad used are included in Figure 5.40. Although less pronounced than in Figure 5.39, the brine phase dispersivity increases as brine phase saturation decreases. Delshad did not use an oil tracer in this particular experiment, so no comparison of oil dispersion can be made.

Experiment OWZ

Experiment OWZ was conducted at 2.0 cc/min nominal flow rate at 30°C using a specially prepared sandpack (Appendix 5 and Table 5.2) in a 2.0 inch diameter steel column. The sandpack was initially saturated with 1.1 wt % NaCl brine.

Dispersion was determined using tritium in the brine phase and carbon-14 labelled n-decane and n-nonane in the n-decane phase. Fluid and sandpack data are contained in Table 5.12. The experimental results appear in Tables 5.13 and 5.14 and Figures 5.41 to 5.76.

Imbibition relative permeability curves for n-decane and brine appear in Figure 5.41. Saturation from tritium breakthrough in the brine phase agrees closely with material balance saturations. Oil saturations by isotope breakthrough, however, are skewed to the right perhaps due to stagnant fluid saturations (Chapter 2). Total relative mobility data is illustrated in Figure 5.42. The minimum is 0.106cp^{-1} and is skewed to the right occurring at residual oil saturation ($S_{or} = 0.134$). The fractional flow diagram (Figure 5.43) is typical of low permeability waterwet unconsolidated sand. The change in shape of total relative mobility and fractional flow curves for the low permeability sandpack compared to a high permeability pack (Figures 5.7 and 5.8) is due to a change in the pore distribution with a much more restrictive flow environment (especially with multiple saturations present) occurring in the low permeability pack.

Table 5.15 contains calcium leaching data from the sandpack for Experiment OWZ. Although some calcium ion is picked up in initial samples it quickly falls to an undetectable concentration (< 5 ppm) and appears to be no problem. The clay removal prior to packing removes most

of the calcium ion source (Appendix 5). Figures 5.44 to 5.48 contain sandpack property determination data and Figures 5.49 to 5.74 contain dispersion data.

The narrow S-shaped curve for 100% brine saturation (Figure 5.44) indicates that the pack contains no significant heterogeneities and the breakthrough time implies that the pore volume is very close to 472.5 cc (Equation 2.9). The close agreement with the saturation pore volume (Table 5.12) is another indication of homogeneity. The single-phase dispersivity is 0.274 cm (Figure 5.45). The next cut consisted of 100% n-decane and resulted in the dispersion curve labelled Tracer A in Figure 5.46. Although early breakthrough and non-ideal S-shape curves were later observed for the oleic phase dispersions in Berea sandstone, the unusual shape of Tracer A was at this time not understood, so the possibility that it was due to heterogeneity of the sandpack was investigated. The sandpack was flooded to residual oil and the resulting dispersion curve (Figure 5.47) is smooth and S-shaped indicating a good pack. The pack was flooded back to residual water with n-decane and a second dispersion (Tracer B) was conducted (Figure 5.46). A third dispersion curve (Tracer C) was determined, this time utilizing a n-nonane tracer. All three curves are essentially identical. At this point the sandpack was cleaned of oil and brine by flushing the pack with four pore volumes of ethylbenzene followed by four pore volumes of

methanol and finally ten pore volumes of 1.1 wt % NaCl brine. This was done to determine if heterogeneity had developed since the initial 100% brine dispersion was determined. The second 100% brine dispersion (OW1Z) appears in Figure 5.49. The curve is smooth and S-shaped indicating a good homogeneous pack. At this juncture, the core was judged to contain no heterogeneity and the unusual appearance of Figure 5.46 was thought to be due to some other mechanism. Note that relative permeability, fractional flow, and mobility data were determined after the cleaning discussed above. A final dispersion curve for oil at residual water appears in Figure 5.51. This curve is similar to those in Figure 5.46 (any differences are probably due to a change in wettability during the cleaning process). The aqueous phase dispersion curves are smooth and S-shaped and brine phase saturations calculated from frontal breakthrough (Equation 2.20) are 0.9 (OW4Z) to 1.3 times the material balance saturations (Table 5.14). The oil phase dispersions, like the high tension Berea results (BAOW), exhibit very early breakthrough and skewed, "capacitance"-type curves. Brine and oil phase dispersivities as a function of brine phase saturation are illustrated in Figure 5.75. Unlike the other experimental results in this investigation, there is little correlation between phase dispersivity and phase saturation. Oil phase dispersivity is two orders of magnitude greater than for the brine phase.

Experiment MO

Experiment MO was conducted in the same sandpack utilized in Experiment OWZ (Appendix 5). The investigation was carried out at 2.0 cc/min nominal flow rate at 30°C using pre-equilibrated oleic and microemulsion phases from a three-phase system. A complete recovery of all oil and brine phases was accomplished by flooding with the microemulsion phase and the flooding series began, therefore, at 100% microemulsion saturation. Carbon-14 labelled n-decane was used as a tracer for the oil phase and tritium for the microemulsion phase. Note that the carbon-14 tracer partitions into the microemulsion phase (see Chapter 2). Fluid and sandpack data are contained in Table 5.16. The partition coefficient determination is given in Table 5.17. The experimental results appear in Tables 5.18 to 5.20 and Figures 5.76 to 5.103.

Relative permeability curves appear in Figure 5.76. Note that although the curves span the entire saturation range, they are not straight lines. In addition, the oil relative permeability curve is more concave than the microemulsion curve. There is a fairly good agreement between the saturation by material balance calculation and the saturation by tritium breakthrough. Also, the 100% oil permeability and 100% microemulsion permeability were both 0.154 Darcy which is lower than the 100% brine permeability (0.467 Darcy). The 100% oleic phase saturation permeability

from Experiment MO and 100% microemulsion phase saturation permeabilities from Experiments MO and MW (Tables 5.18 and 5.21) are all very close to 0.154 Darcy. This fact, along with the observation of rust in initial effluent samples after the porous medium was shut in, leads to suspicion of permeability reduction from the original 100% brine permeability (0.467 Darcy). As a result all effective permeabilities are normalized by 100% microemulsion permeability in Experiments MO, MW, and PH3 to obtain relative permeability. Figure 5.77 compares the relative permeability curves with the high tension experiment (OWZ) relative permeability curves. Microemulsion relative permeability is higher than brine phase relative permeability. Oleic phase relative permeability, on the other hand, is approximately equal to n-decane relative permeability. The range of saturation increases to encompass the entire range. Total relative mobility data is illustrated in Figure 5.78. The minimum is 0.213 cp^{-1} and occurs at 0.831 microemulsion saturation. A fractional flow diagram appears in Figure 5.79 and is linear from approximately 0.30 to 1.0 microemulsion saturation. Figure 5.80 illustrates the widening of the saturation range for micellar fluids compared to high IFT fluids. Table 5.20 contains calcium leaching data. As for Experiment OWZ, calcium leaching is not significant. Dispersion data for Experiment MO appears in Figures 5.81 to 5.102.

The narrow S-shaped curve for 100% microemulsion saturation (Figure 5.81) indicates once again that the sandpack was homogeneous. The single-phase dispersivity is 0.274 cm (Figure 5.82). The microemulsion dispersion curves are smooth and S-shaped. Microemulsion phase saturations calculated from frontal breakthrough (Equation 2.20) are 1.1 to 1.3 times the material balance saturations (Table 5.19). The oil phase dispersions, unlike high tension oil phases, do not exhibit early breakthrough times and are more S-shaped. The 100% oleic phase dispersion (Figure 5.101) again reflects a homogeneous pack. The single-phase oleic dispersivity is 0.21 cm (Figure 5.102). Oleic phase dispersivity based on Equation 2.33 and measured from apparent carbon-14 dispersivity ($\bar{\alpha}$) in both phases yields essentially the same result. The equations for cut M04 appear below:

$$2.09 = \frac{0.577 \alpha_{22} + (0.443) \alpha_{23} (0.486)}{0.577 + (0.443)(0.486)} \quad 5.1$$

$$1.98 = \frac{0.577 \alpha_{22} + (0.443) \alpha_{23} (0.486)}{0.577 + (0.443)(0.486)} \quad 5.2$$

$$0.229 = \frac{0.443 \alpha_{13} + (0.557) \alpha_{12} (0)}{0.443 + (0.557)(0)} \quad 5.3$$

Equations 5.1 and 5.2 yield the same result. Since there are three unknown quantities (α_{22} , α_{23} , α_{13}) and three equations, the system is determinate. Since two equations are the same, this implies that two unknowns are also the same. Oleic phase dispersivity and microemulsion phase dispersivity are not equal. Therefore microemulsion phase dispersivity measured by tritium (α_{13}) is equal to microemulsion phase dispersivity measured by carbon-14 (α_{23}).

Oleic phase saturations calculated by Equation 2.25 are negative. A negative value has no physical meaning so the theory apparently does not apply in this case. Oleic phase saturations based on a non-partitioning tracer (Equation 2.20), however, are in close agreement for both microemulsion and oleic phases (Table 5.19).

Microemulsion and oleic phase dispersivities as a function of microemulsion phase saturation are illustrated in Figure 5.103. As before, oleic phase dispersion increases as oleic phase saturation decreases. Microemulsion phase dispersivity, on the other hand, remains approximately constant with changing microemulsion phase saturation.

A comparison of high and low IFT dispersivities appears in Figure 5.104. Microemulsion and brine dispersivities are approximately equal. Oleic phase dispersivity is about equal to microemulsion dispersivity at 100% oleic phase saturation and increases, approaching the n-decane dispersivity values, as the oleic phase saturation decreases.

Table 5.16 contains data on injected phase compositions. Figures 5.105 and 5.106 illustrate the composition (by gas chromatography) of effluent phases for steady-state dispersion determinations. Figure 5.107 contains interfacial tension data for these same cuts. It appears that steady-state was achieved for this experiment.

Experiment MW

Experiment MW was also carried out in the same sandpack (Appendix 5). The investigation was conducted at a nominal flow rate of 2.0 cc/min at 30°C using pre-equilibrated brine and microemulsion phases from the same three-phase system as before. The fluids were injected in the direction of decreasing brine cuts. Carbon-14 labelled n-decane was utilized as a tracer for the microemulsion phase and tritium for the aqueous phase. Note that the tritium tracer partitions into the microemulsion phase (see Chapter 2) while the carbon-14 tracer is non-partitioning. Fluid and sandpack data are contained in Table 5.16. Partition coefficient determination data are given in Table 5.17.

Relative permeability curves appear in Figure 5.108. The curves indicate a residual microemulsion saturation of 0.113. The 100% microemulsion permeability is 0.154 Darcy, which is lower than the 100% brine permeability (see Experiment MO). Material balance saturations and saturation by carbon-14 breakthrough are very close. Figure 5.109

compares high IFT relative permeabilities with those obtained in this experiment. Aqueous phase relative permeability is higher and covers a larger saturation range. The microemulsion phase, although it covers a larger saturation range, is very close to n-decane relative permeability. Total relative mobility data is illustrated in Figure 5.110. The minimum is 0.213 cp^{-1} at 0.137 aqueous phase saturation. A fractional flow diagram appears in Figure 5.111. The shape of the curve has a convex character. High IFT brine-phase fractional flow is compared to low tension aqueous-phase fractional flow in Figure 5.112. The widening of saturation range and change in shape is apparent. Table 5.20 contains calcium leaching data. As before, calcium leaching is not significant. Dispersion data for Experiment MW appears in Figures 5.113 to 5.134.

The microemulsion dispersion curves are smooth and S-shaped. Microemulsion phase saturations calculated from frontal breakthrough times (Equation 2.20) are 1.02 to 1.2 times the saturations calculated by material balance (Table 5.22). The aqueous phase dispersion curves are more irregularly shaped than the microemulsion phase curves. As in Experiment MO, aqueous phase saturations calculated by Equation 2.25 are negative values. The theory apparently does not apply in this case. Saturations based on a non-partitioning tracer yield fairly good approximations of material balance saturations being 1.1 to 1.4 times greater

than saturations calculated from material balance (Table 5.22). Aqueous phase dispersivities calculated from the partitioning tritium tracer are in close agreement for both microemulsion and aqueous phases. Microemulsion and aqueous phase dispersivities as a function of aqueous phase saturation are illustrated in Figure 5.135. Aqueous phase dispersivity increases as aqueous phase saturation decreases. Microemulsion phase dispersivity remains essentially unchanged with decreasing saturation. A comparison of high and low IFT dispersivities appears in Figure 5.136. As before, microemulsion and brine dispersivities are approximately equal. As aqueous phase saturation decreases, the magnitude of aqueous phase dispersivity increases to the same magnitude as n-decane dispersivity. Table 5.16 contains data on injected phase compositions. Figures 5.137 and 5.138 illustrate the composition (by gas chromatography) of effluent phases for steady-state dispersion determinations. Figure 5.139 contains IFT data for these same cuts. It appears that steady-state was achieved for this experiment.

Experiment PH3

Experiment PH3 utilized the same specially prepared sandpack (Appendix 5). The investigation was conducted at 2.0 cc/min nominal flow rate at 30°C using pre-equilibrated aqueous, microemulsion, and oleic phases from a three-phase system. The experimental flooding sequence proceeds from

predominantly oleic phase saturation to predominantly aqueous phase saturation with approximately constant microemulsion saturation. This was done to resemble the imbibition phenomenon. Carbon-14 labelled n-decane in microemulsion phase, n-nonane in oleic phase, and tritium in aqueous phase were the tracers utilized. Note that tritium partitions between microemulsions and aqueous phases while n-nonane and carbon-14 labelled n-decane partition between microemulsion and oleic phases (see Chapter 2). Fluid and sandpack data are contained in Table 5.16. Partition coefficient data is contained in Table 5.17.

The saturation history of PH3 appears in Figure 5.140. There are three two-phase endpoints and three three-phase points.

Relative permeability of phase j as a function of phase j saturation for oleic, microemulsion, and aqueous phases appears in Figure 5.141. As expected, the microemulsion phase relative permeabilities are essentially unchanged since the microemulsion cut was kept constant during the experiment. Aqueous and oleic phase relative permeabilities, on the other hand, appear to be approximately equal and dependent on their individual saturations. Oleic and aqueous phase saturations are about the same as in the two-phase experiments (Figures 5.76 and 5.108). Total relative mobility as a function of aqueous phase saturation is illustrated in Figure 5.142. The minimum is 0.149 cp^{-1}

at 0.324 aqueous, 0.515 microemulsion, and 0.161 oleic phase saturations. Fraction flow of phase j as a function of phase j saturation appears in Figure 5.143. Aqueous and oleic phase fractional flows are approximately equal. Additional data at different microemulsion cuts will be necessary before its behavior can be characterized. Calcium leaching was insignificant (Table 5.20). Dispersion data appears in Figures 5.144 to 5.177.

Single aqueous phase dispersion at residual microemulsion (Figure 5.144) is smooth and S-shaped. Oleic phase dispersion at residual aqueous phase saturation (Figure 5.146) is also smooth and S-shaped and demonstrates that *n*-nonane works well as a non-partitioning tracer. The dispersion curves for three-phase flow with partitioning tracers are all S-shaped. Tracers that partition into the microemulsion phase (*n*-nonane and tritium) tend to demonstrate more scatter in the microemulsion phase. *N*-nonane in microemulsion was not measured due to insufficient phase volumes and carbon-14 dispersion in cut PH35 in the oleic phase was not measured due to loss of samples. Finally, aqueous phase at residual microemulsion (Figure 5.176) is very close to the initial saturation (Figure 5.144). Saturations calculated from frontal breakthrough times (Equation 2.20) are very close to material balance saturations for cuts PH31, PH32, PH33, and PH36. Aqueous phase saturations are moderately larger in PH34

and substantially larger in PH35. The reverse is true of microemulsion saturation at these two cuts. Oleic saturations are within 20 percent of material balance saturations in PH34 and PH35 (Table 5.24). Saturations calculated by Equation 2.25 are negative. As before, the theory apparently does not apply in this case. Dispersivity of tracer i as a function of phase j saturation is illustrated in Figures 5.178 and 5.179. Ideally, three tracers are needed to calculate three dispersivities. Using Equation 2.33 to calculate dispersivity results in negative values. The n -nonane tracer gave inconsistent average dispersivities and apparently is not suitable where partitioning occurs. Since microemulsion dispersivity is approximately 0.2 cm in Experiments MO and MW, it will be assumed to be this value in this experiment as well. Oleic and aqueous phase dispersivities are calculated from Equation 2.33 using this microemulsion phase dispersivity. It would appear that phase dispersivity increases as phase saturation decreases for the oleic and aqueous phases. It is also apparent that inconsistent results occur for the n -nonane tracer. Table 5.23 contains data on injected phase compositions. Figures 5.180 to 5.182 illustrate the composition (by gas chromatography) of effluent phases for steady state dispersion determinations. Figures 5.183 and 5.184 contain IFT data for these same cuts. It appears that steady state was achieved for this experiment.

General Comments

If a material balance is performed on those high IFT oleic phase cases in BAOW and OWZ where early oleic phase tracer breakthrough occurred, it would appear that more tracer is produced than injected. This anomaly can be explained if the plateau tracer concentration is lower than injected concentration. This situation is confirmed in Table 5.26 which contains data on those cuts where these two concentrations were measured. Brine phase plateau concentrations are close to injected, but oleic phase concentrations are significantly lower. This suggests that some of the oleic phase (presumed non-wetting) is being bypassed during the flooding.

A comparison of residual phase saturations as a function of capillary number (defined two different ways) appears in Figures 5.185 and 5.186. At the high capillary numbers attained in this investigation, all residual saturations are zero except for residual microemulsion saturation to brine which is, however, much lower than residual microemulsion saturation to brine in Berea.²⁸ This would imply that microemulsion is the wetting phase.

FIGURE 5.186 -- Residual Phase Saturations as a Function of Capillary Number

SUMMARY AND CONCLUSIONS

A brief review of high and low IFT relative permeability and dispersion is presented. Existing dispersion theory is generalized to include the effects of two- and three-phase flow and partitioning tracers. One-, two-, and/or three-phase flow experiments were carried out in sand-packs and Berea sandstone to measure relative permeability and phase dispersivity for both high and low IFT formulations. Relative permeability is measured at steady-state phase fractions followed by injection of a tracer in each flowing phase while at steady-state. Phase saturation and dispersivity are calculated from tracer effluent data. Saturations are also calculated by material balance.

Phase behavior, IFT, and viscosity behavior of Siponate DS-10 and TRS 10-410 formulations were investigated with several alcohol co-surfactants and at several salinities. Siponate DS-10 was determined to be unsuitable for our studies at the compositions investigated, but TRS 10-410 formulations are acceptable. The micellar formulation used in the low IFT flow experiments consists of TRS 10-410 sulfonate, isobutanol, n-decane, and 1.1 wt % NaCl brine. Interfacial tensions between microemulsion and excess brine and microemulsion and excess oil are on the order of 10^{-3} dyne/cm.

The following conclusions can be stated concerning dispersion for the high IFT systems studied:

1. Dispersivity of tritium in the brine phase increases with decreasing brine phase saturation in Berea and the sandpack used in Experiment OW, but no relationship was demonstrated in the sandpack used in Experiment OWZ.
2. Dispersivity of carbon-14 in the oil phase increases with decreasing oil phase saturation in Berea but shows no relationship in the sandpack used in Experiment OWZ.
3. Oil phase dispersivity is two orders of magnitude greater than brine phase dispersivity in the sandpack used in Experiment OWZ.
4. Brine phase tracer breakthrough curves were smooth and S-shaped and gave saturations in good agreement with material balance.
5. Oil phase tracer breakthrough curves have more of a capacitance-type shape (Chapter 2) and demonstrate early breakthrough resulting in poor agreement with saturations calculated by material balance. (Note that capacitance may account in part for Result 3.)
6. Plateau tracer concentration is very close to injected concentration in the brine phase, but is lower in the oil phase. This result, along with the early breakthrough of oil phase, could indicate the existence of a non-contacted oil volume that

gains tracer by a relatively slow diffusion process compared to the convective process.

The following conclusions can be drawn from the relative permeability studies in the low IFT experiments:

7. Relative permeability increased, but there was significant curvature in both two- and three-phase relative permeability curves.
8. Residual phases in the sand pack at low tension were zero except for residual microemulsion to aqueous phase.
9. Result 8 along with changes in fractional flow diagrams and the essentially identical relative permeability of oleic and aqueous phases in three-phase flow indicate a change in wettability from the initial water-wet state.
10. In three-phase flow, aqueous and oleic phase relative permeabilities appear to be a function of their own saturation. Insufficient data exists for the microemulsion phase.
11. Dispersivity of oleic and aqueous phases increases with decreasing phase saturation.
12. Microemulsion phase dispersivity is essentially unchanged with decreasing microemulsion saturation.

13. Dispersivities measured by partitioning tracers were consistent between the tritiated water and carbon-14 labelled n-decane, but not with n-nonane in n-decane.

The following general conclusions can be drawn:

14. Calcium ion concentration was not significant in the treated sandpack.
15. The composition and IFT analyses of effluent samples (pressure drop and phase volume fractions were constant in all cases) confirm that steady state was achieved with the micellar phases.

More data is needed to confirm and expand the tentative conclusions drawn.

NOMENCLATURE

A	=	Cross sectional area (cm^2)
$C_{O_{ij}}$	=	Injected concentration of component i in phase j
$C_{T_{ij}}$	=	Concentration of component i in phase j
$C_{D_{ij}}$	=	Normalized concentration of component i in phase j
D_O	=	Molecular diffusion coefficient (cm^2/sec)
F	=	Formation electrical resistivity factor
f_j	=	Fractional flow of phase j
K_l	=	Longitudinal dispersion coefficient (cm^2/sec)
K_{ij}	=	Longitudinal dispersion coefficient of tracer i in phase j (cm^2/sec)
K_t	=	Transverse dispersion coefficient (cm^2/sec)
\bar{K}_i	=	Average dispersion coefficient of component i (cm^2/sec)
K_{T_i}	=	Partition coefficient of component i
k	=	Absolute permeability (D)
k_{ej}	=	Effective permeability of phase j (D)
k_{rj}	=	Relative permeability of phase j

- L = Total length of porous medium (cm)
- M = Mobility (cp^{-1})
- M_{rT} = Total relative mobility
- N_c = Capillary number
- q = Flow rate (cm^3/sec)
- S_j = Saturation of phase j
- S_{rj} = Residual saturation of phase j
- t_D = Time (pore volumes)
- t_D^{Bt} = Time where $C_i/C_{oi} = 0.5$ (pore volume)
- t_{Dt} = Time normalized for phase fractional flow and saturation in multiphase flow (pore volumes)
- U_j = Darcy velocity of phase j (cm/sec)
- V = Volume of produced effluent (cm^3)
- V_p = Pore volume of porous medium (cm^3)
- v_{Tj} = Average interstitial velocity of phase j (cm/sec)
- α_1 = Longitudinal dispersivity (cm)
- α_{ij} = Longitudinal dispersivity of tracer i in phase j (cm)
- $\bar{\alpha}_i$ = Average dispersivity of component i (cm)

β = Velocity exponent

ϕ = Porosity (cm^3/cm^3)

λ = Dimensionless function $\frac{t_D - 1}{\sqrt{t_D}}$

λ_1 = Dimensionless function $\frac{t_{Dt} - 1}{\sqrt{t_{Dt}}}$

μ_j = Viscosity of phase j (cp)

σ = Interfacial tension (dyne/cm)

$\Delta\phi_j$ = Potential difference of phase j (psi)

Subscripts

i = component

i = 1, tritium tracer

i = 2, carbon-14 tracer

i = 2', n-nonane tracer

j = phase

j = 1 or W, aqueous phase

j = 2 or O, oleic phase

j = 3 or ME, microemulsion phase

APPENDIX 1

Construction of Volume Fraction Diagrams

Sample tubes are made up as outlined in Chapter 4 and allowed to reach equilibrium. The volume of each phase is divided by the total phase volume. The resulting phase volumes total 1.0. These points are plotted as in Figure 3.2 with lines connecting the points corresponding to aqueous microemulsion and microemulsion-oleic phase boundaries.

APPENDIX 2

Construction of Pseudo-Ternary Diagrams

Using Tie-lines

Figure A2.1³⁷ illustrates the relationship between distance on the pseudo-ternary diagram and phase volumes of sample tubes. The solid point represents the overall composition. Type II phase compositions correspond to where the tie-lines meet the two-phase envelope. In the ideal Type III phase region, the phases are invariant at constant temperature and pressure and consist of almost pure oil, almost pure brine, and a microemulsion phase of a composition indicated where the one-, two-, and three-phase regions meet (invariant point).

FIGURE A2.1

TERNARY REPRESENTATION OF PHASE RELATIONSHIPS

APPENDIX 3

Epoxy Mixing Procedure

Resin (R-829) and hardener (Versamid 125) are available from the Ring Chemical Company. The following procedure is repeated three times:

1. Weigh 70 wt % resin and 30 wt % hardener into a beaker.
2. Stir for five minutes until homogeneous.
3. Pour into a shallow container (such as aluminum foil tray) and allow to set for two hours to attain the proper consistency and to allow air bubbles to escape.
4. Apply epoxy to core as a thin layer.
5. Allow to harden for 24 hours.

APPENDIX 4

Pore Volume by Grain Density

If the weight of sand that is packed into a column of known bulk volume is known, the pore volume can be calculated from the grain density. First, grain density is measured and then the formula for calculating pore volume is presented.

A known weight of sand is weighed into a previously weighed 100 ml volumetric flask. The flask is then filled up to the mark with distilled water and the temperature recorded. Grain density is:

$$\rho_g = \frac{WT \text{ g}}{100 - \frac{WT_{H_2O}}{\rho_{H_2O}}} \quad A4.1$$

The actual values were:

volumetric weight = 70.28

volumetric + sand weight = 126.02 g

weight of sand (WT g) = 55.74 g

volumetric + sand + H₂O = 204.61 g

weight of water (WT_{H₂O}) = 78.59 g

water density at 25°C = .99705 g/ml

$$\rho_g = \frac{55.74 \text{ g}}{100 \text{ ml} - \frac{78.59 \text{ g}}{.99705 \text{ g/ml}}} = 2.632 \text{ g/ml}$$

Pore volume and porosity can be calculated as follows:

$$V_P = \left(V_B - \frac{WT_{sand}}{\rho_g} \right) \quad A4.2$$

$$\phi = \frac{V_P}{V_B} = 1 - \frac{WT_{sand}}{\rho_g V_B} \quad A4.3$$

APPENDIX 5

Special Sand Preparation

Ottawa F140 sand (Table 5.1) was divided into component mesh sizes by mechanical shaking. The following mesh sizes were used along with a 400 mesh silica sand supplied by Fisher Scientific Inc.:

<u>Mesh</u>	<u>Grams</u>	<u>Weight Percent</u>
200	246	11.7
230	260	12.4
270	490	23.3
270+	294	14.0
400	810	38.6

Each mesh size was washed twice in concentrated hydrochloric acid and washed repeatedly with distilled water to neutral pH. The sands were then subjected to sonication for two hours and dried for 48 hours at 110°C. This procedure effectively removed clays from the sand particles (Table 5.45). The mesh mixture mixed well and no segregation of sand was discernable.

VITA

Donald James MacAllister was born in Muleshoe, Texas, on January 27, 1953, the son of Neal Daniel MacAllister and Chrys Faye MacAllister. After graduation from Coronado High School, Lubbock, Texas, in 1971, he entered The University of Texas at Austin, Texas. As an undergraduate he co-authored publications for the Society of Petroleum Engineers of AIME and the Journal of Colloid and Interface Science. He received a Bachelor of Science in Chemistry degree in December, 1974, and entered Southwestern Medical School in August, 1975. Feeling that he was more suited to the recovery of oil than the recovery of people, he entered the Graduate School at The University of Texas in September, 1979, after a short stint at Core Laboratories.
